Complement component I (1F) and C1R subcomponent Abstract of C1 (C1R) types were determined by isoelectric focusing and subsequent immunoblotting techniques for 658 individuals from nine aboriginal Taiwanese populations. The frequency of the IF\*A allele ranges from 0.075 (Bunun) to 0.430 (Saisiat), and a new variant allele IF\*B2 was found to have polymorphic frequency in the Atayal. The frequency of the C1R\*1 allele ranges from 0.410 (Yami) to 0.650 (Atayal), and the frequency of the CIR\*2 allele ranges from 0.265 (Atayal) to 0.586 (Saisiat). The CIR\*5 allele was found in five populations (Atayal, Bunun, Ami, Puyuma, Yami), and the C1R\*9 allele was found in two populations (Tsou, Puyuma). The results indicate a remarkable degree of genetic variability among these populations. The variability may reflect long-term genetic and geographic isolation of each population.

The aboriginal populations of Taiwan (Kaoshan, Mountain Highlander) in 1985 consisted of about 320,000 people, making up 1.5% of the total population of Taiwan (Dai 1988). Nine aboriginal tribes are commonly recognized as linguistically and culturally distinct groups. Polymorphisms using various genetic markers have been analyzed in some of these tribes (Huang 1964; Ikemoto et al. 1966; Nakajima and Ohkura 1971; Nakajima et al. 1971; Chen et al. 1985), and it is inferred that they belong to the southern group of Mongoloids. However, the precise genetic origin of each tribe and their mutual relationships are not fully

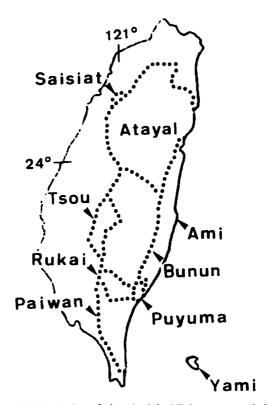

Figure 1. Geographic distribution of nine aboriginal Taiwanese populations.

resolved. To elucidate these problems, we collected blood samples from all nine aboriginal populations in 1990 and 1991. Here, we report a pilot study of polymorphisms of two serum proteins in these nine tribes.

The systems chosen were complement component I (IF) and the C1R subcomponent of the first complement component (C1R), described by Nakamura and Abe (1985) and Kamboh and Ferrell (1986), respectively. Only limited population studies have been performed with these genetic markers so far.

## Materials and Methods

Blood samples were collected from 658 unrelated healthy individuals in the following aboriginal Taiwanese populations: Atayal (100), Saisiat (64), Bunun (87), Tsou (80), Ami (72), Puyuma (63), Rukai (54), Paiwan (60), and Yami (78). Their geographic locations are shown in Figure 1.

Plasma samples were treated with fourfold volumes of sialidase (0.5 U/ml; type V, Sigma, St. Louis, Missouri; pH 5.0) at room temperature overnight. The IF typing was carried out by agarose gel isoelectric focusing (IEF) followed by immunoblotting, as described elsewhere (Ding et al. 1991).

For C1R typing polyacrylamide gels (5% total acrylamide concentration, 3% cross-linker ratio, 220 × 120 × 0.3 mm) were prepared containing 2.4% Ampholine (pH 5-8) (Pharmacia, Uppsala, Sweden), 6 M urea, and 10% glycerol. The anodic and cathodic solutions were 1 M H<sub>2</sub>PO<sub>4</sub> and 1 N NaOH, respectively. The gel was prerun for 30 min at 12°C and at a constant power supply of 5 W. Once samples (4 µl) had been applied, focusing was continued for 2.5 hr at a constant power supply of 10 W. After IEF, proteins were passively transferred to a Immobilon-P membrane (Millipore, Bedford, Massachusetts). After 60 min of blotting, the filters were removed, treated with a quenching buffer [phosphate-buffered saline (PBS) containing 3% skim milk and 0.01% Tween 20] for 20 min, and incubated for 60 min with peroxidaseconjugated anti-human C1R goat serum diluted 1:200 in PBS. The goat anti-human C1R serum (Binding site, Birmingham, England) was coupled with horseradish peroxidase (type I-C; Toyobo, Osaka, Japan) according to the method of Nakane (1975). The membranes were washed 3 times for 5 min with PBS containing 0.01% Tween 20. The immune complexes formed on the membranes were stained with diaminobenzidine.

### Results

The distribution of IF phenotypes is shown in Table 1. Three common phenotypes were observed, which could be explained by two alleles, IF\*A and IF\*B. The IF\*A allele frequency varied from 0.075 (Bunun) to 0.430 (Saisiat) among the nine aboriginal Taiwanese populations (see Table 2). The frequency of the IF\*A allele in the Saisiat was the highest among all populations studied so far, whereas the frequency in the Bunun was one of the lowest levels in Mongoloids (Table 2). In addition to the common phenotypes, a new variant was encountered in 5 of 100 Atayal samples and was designated as IF B2. The variant band migrated slightly cathodal to the IF B band (Figure 2). The observed phenotypic distribution was in good agreement with Hardy-Weinberg expectation.

The distribution of C1R phenotypes is summarized in Table 3. Seven different phenotypic patterns explained by four alleles were observed. The symbols of these alleles were based on the nomenclature proposed by Kamboh et al. (1989) and Kido et al. (1991). In the nine populations the observed numbers were in accordance with the numbers expected under Hardy-Weinberg equilibrium. The frequency of the C1R\*1 allele

n: sample size.

Figure 2. Immunoblotted band patterns of IF phenotypes. From left to right: IF B, IF B,B2, IF A, IF A,B, IF B, IF B,B2, and IF A,B. Anode is at the top. Open triangle indicates major variant band.

ranges from 0.410 (Yami) to 0.650 (Atayal), and that of the C1R\*2 allele ranges from 0.265 (Atayal) to 0.586 (Saisiat). The frequency of the C1R\*5 allele was highest (0.085) in the Atayal, but that allele was not observed in the Saisiat, Tsou, Rukai, and Paiwan. A variant allele, C1R\*9, was found in the Tsou and Puyuma with frequencies of 0.013 and 0.008, respectively. The C1R allele frequencies in various populations are listed in Table 4. Although the C1R\*5 allele is widely distributed in blacks and Mongoloids, the C1R\*9 allele has been observed so far only among Japanese (Nakamura et al. 1988; Kido et al. 1991).

#### Discussion

The gene diversity  $(G_{ST})$  between populations (Nei 1987) was estimated to be 0.0343 based on the present data. This large  $G_{ST}$  value indicates that a significant degree of genetic variability exists among the nine tribes, although only two protein polymorphisms of the complement system were analyzed in this study. Such a great diversity in native populations in Taiwan suggests that there were several migrations to Taiwan from different populations of neighboring regions, such as mainland China and Southeast Asia. If those migrations had occurred a relatively long time ago, low levels of gene flow between populations might also have been a factor producing such large genetic differentiation between these aboriginal Taiwanese populations. In any case, further examination of many more genetic polymorphisms is necessary to test this hypothesis.

Table 3. Distribution of CIR Phenotypes in Nine Aboriginal Taiwanese Populations<sup>4</sup>

n: sample size.

Akcnowledgments We thank S. Nakamura, Department of Legal Medicine, Tokyo Women's Medical College, for providing reference samples. This research was supported by Grants-in-Aid from the International Research Program ("Human Genetic Studies on Native Minority Groups in Taiwan") and by a Scientific Research on the Priority Area grant ("Prehistoric Mongoloid Dispersals") from the Ministry of Education, Science, and Culture of Japan.

Received 15 December 1992; revision received 21 April 1993.
